Package ‘cna’

December 17, 2021

Type Package

Title Causal Modeling with Coincidence Analysis

Version 3.3.0

Date 2021-12-17

Description Provides comprehensive functionalities for causal modeling with Coincidence Analysis (CNA), which is a configurational comparative method of causal data analysis that was first introduced in Baumgartner (2009) <doi:10.1177/0049124109339369>, and generalized in Baumgartner & Ambuehl (2018) <doi:10.1017/psrm.2018.45>. CNA is designed to recover INUS-causation from data, which is particularly relevant for analyzing processes featuring conjunctural causation (component causation) and equifinality (alternative causation). CNA is currently the only method for INUS-discovery that allows for multiple effects (outcomes/endogenous factors), meaning it can analyze common-cause and causal chain structures.

Description

*Coincidence Analysis* (CNA) is a configurational comparative method of causal data analysis that was first introduced for crisp-set (i.e. binary) data in Baumgartner (2009a, 2009b, 2013) and generalized for multi-value and fuzzy-set data in Baumgartner and Ambuehl (2020). The *cna* package implements the method’s latest stage of development.
CNA infers causal structures as defined by modern variants of the so-called *INUS-theory* (Mackie 1974; Grasshoff and May 2001; Baumgartner and Falk 2019) from empirical data. The INUS-theory is a type-level difference-making theory that spells out causation in terms of redundancy-free Boolean dependency structures. It is optimally suited for the analysis of causal structures with the following features: *conjunctivity*—causes are arranged in complex bundles that only become operative when all of their components are properly co-instantiated, each of which in isolation is ineffective or leads to different outcomes—and *disjunctivity*—effects can be brought about along alternative causal routes such that, when suppressing one route, the effect may still be produced via another one.

Causal structures featuring conjunctivity and disjunctivity pose severe challenges for methods of causal data analysis. As many theories of causation (other than the INUS-theory) entail that it is necessary (though not sufficient) for X to be a cause of Y that there be some kind of dependence (e.g. probabilistic or counterfactual) between X and Y, standard methods—most notably Bayesian network methods (Spirtes et al. 2000)—infer that X is *not* a cause of Y if X and Y are *not* pairwise dependent. However, there are no dependencies between an individual component X of a conjunctive cause and the corresponding effect Y (for concrete examples see the package vignette (accessed from R by typing `vignette("cna")`). In the absence of pairwise dependencies, X can only be identified as a cause of Y if it is embedded in a complex Boolean structure over many factors and that structure is fitted to the data as a whole. But the space of Boolean functions over even a handful of factors is vast. So, a method for INUS-discovery must find ways to efficiently navigate in that vast space of possibilities. That is the purpose of CNA.

CNA is not the only method for the discovery of INUS structures. Other methods that can be used for that purpose are Logic Regression (Ruczinski et al. 2003, Kooperberg and Ruczinski 2005), which is implemented in the R package *LogicReg*, and Qualitative Comparative Analysis (Ragin 1987; 2008; Cronqvist and Berg-Schlosser 2009), whose most powerful implementations are provided by the R packages *QCApro* and *QCA*. But CNA is the only method of its kind that can process data generated by causal structures with more than one outcome and, hence, can analyze common-cause and causal chain structures as well as causal cycles and feedbacks. Moreover, unlike the models produced by Logic Regression or Qualitative Comparative Analysis, CNA’s models are guaranteed to be redundancy-free, which makes them directly causally interpretable in terms of the INUS-theory; and CNA is more successful than any other method at exhaustively uncovering all INUS models that fit the data equally well. For comparisons of CNA with Qualitative Comparative Analysis and Logic Regression see (Baumgartner and Ambuehl 2020) and (Baumgartner and Falk 2021), respectively.

There exist two additional R packages for data analysis with CNA: *cnaOpt*, which systematizes the search for optimally fitting CNA models, and *frscore*, which automatizes robustness scoring of CNA models.

allCombs

---

**Description**

The function `allCombs` generates a data frame of all possible value configurations of `length(x)` factors, the first factor having `x[1]` values, the second `x[2]` values etc. The factors are labeled using capital letters.

**Usage**

```r
allCombs(x)
```

**Arguments**

- `x` Integer vector with values >0

**Details**

In combination with `selectCases`, `makeFuzzy`, and `is.submodel`, `allCombs` is useful for simulating data, which are needed for inverse search trials benchmarking the output of `cna`. In a nutshell, `allCombs` generates the space of all logically possible configurations of the factors in an analyzed factor set, `selectCases` selects those configurations from this space that are compatible with a given data generating causal structure (i.e. the ground truth, which can be randomly generated using `randomConds`), `makeFuzzy` fuzzifies those data, and `is.submodel` checks whether the models returned by `cna` are true of the ground truth.

The `cna` package provides another function to the same effect, `full.ct`, which is more flexible than `allCombs`.

**Value**

A data frame.

**See Also**

`selectCases`, `makeFuzzy`, `is.submodel`, `randomConds`, `full.ct`
Examples

# Generate all logically possible configurations of 5 dichotomous factors named "A", "B", # "C", "D", and "E".
allCombs(c(2, 2, 2, 2, 2)) - 1

# allCombs(c(2, 2, 2, 2, 2)) generates the value space for values 1 and 2, but as it is # conventional to use values 0 and 1 for Boolean factors, 1 must be subtracted from # every value output by allCombs(c(2, 2, 2, 2, 2)) to yield a Boolean data frame.

# Generate all logically possible configurations of 5 multi-value factors named "A", "B", # "C", "D", and "E", such that A can take on 3 values {1,2,3}, B 4 values {1,2,3,4}, # C 3 values etc.
dat0 <- allCombs(c(3, 4, 3, 5, 3))
head(dat0)
nrow(dat0) # = 3*4*3*5*3

# Generate all configurations of 5 dichotomous factors that are compatible with the causal # chain (A*b + a*B <-> C)*(C*d + c*D <-> E).
dat1 <- allCombs(c(2, 2, 2, 2, 2)) - 1
(dat2 <- selectCases("(A*b + a*B <-> C)*(C*d + c*D <-> E)", dat1))

# Generate all configurations of 5 multi-value factors that are compatible with the causal # chain (A=2*B=1 + A=3*B=3 <-> C=1)*(C=1*D=2 + C=4*D=4 <-> E=3).
dat1 <- allCombs(c(3, 3, 4, 4, 3))
dat2 <- selectCases("(A=2*B=1 + A=3*B=3 <-> C=1)*(C=1*D=2 + C=4*D=4 <-> E=3)", dat1)
nrow(dat1)
nrow(dat2)

# Generate all configurations of 5 fuzzy-set factors that are compatible with the causal # structure A*b + C*D <-> E, such that con = .8 and cov = .8.
dat1 <- allCombs(c(2, 2, 2, 2, 2)) - 1
dat2 <- makeFuzzy(dat1, fuzzvalues = seq(0, 0.45, 0.01))
(dat3 <- selectCases1("A*b + C*D <-> E", con = .8, cov = .8, dat2))

# Inverse search for the data generating causal structure A*b + a*B + C*D <-> E from # fuzzy-set data with non-perfect consistency and coverage scores.
set.seed(3)
groundTruth <- "A*b + a*B + C*D <-> E"

dat1 <- allCombs(c(2, 2, 2, 2, 2)) - 1
dat2 <- makeFuzzy(dat1, fuzzvalues = 0:4/10)
dat3 <- selectCases1(groundTruth, con = .8, cov = .8, dat2)
ana1 <- cna(dat3, outcome = "E", con = .8, cov = .8)
any(is.submodel(asf(ana1)$condition, groundTruth))

\begin{verbatim}
Perform Coincidence Analysis
\end{verbatim}

Description

The cna function performs Coincidence Analysis to identify atomic solution formulas (asf) consisting of minimally necessary disjunctions of minimally sufficient conditions of all outcomes in the
data and combines the recovered asf to complex solution formulas (csf) representing multi-outcome structures, e.g. common-cause and/or causal chain structures.

Usage

```r
cna(x, type, ordering = NULL, strict = FALSE, outcome = TRUE,
    con = 1, cov = 1, con.msc = con,
    notcols = NULL, rm.const.factors = TRUE, rm.dup.factors = TRUE,
    maxstep = c(3, 4, 10), inus.only = only.minimal.msc && only.minimal.asf,
    only.minimal.msc = TRUE, only.minimal.asf = TRUE,
    maxSol = 1e6, suff.only = FALSE,
    what = if (suff.only) "m" else "ac", cutoff = 0.5,
    border = c("down", "up", "drop"), details = FALSE,
    acyclic.only = FALSE, cycle.type = c("factor", "value"))
```

### S3 method for class 'cna'
```
print(x, what = x$what, digits = 3, nsolutions = 5,
    details = x$details, show.cases = NULL, inus.only = x$inus.only,
    acyclic.only = x$acyclic.only, cycle.type = x$cycle.type,
    verbose = FALSE, ...)
```

Arguments

- **x**: Data frame or configTable (as output by `configTable`).
- **type**: Character vector specifying the type of `x`: "auto" (automatic detection; default), "cs" (crisp-set), "mv" (multi-value), or "fs" (fuzzy-set).
- **ordering**: Character string or list of character vectors specifying the causal ordering of the factors in `x`.
- **strict**: Logical; if TRUE, factors on the same level of the causal ordering are not potential causes of each other; if FALSE, factors on the same level are potential causes of each other.
- **outcome**: Character vector specifying one or several factor values that are to be considered as potential outcome(s). For crisp- and fuzzy-set data, factor values are expressed by upper and lower cases, for multi-value data, they are expressed by the "factor=value" notation. Defaults to outcome = TRUE, which means that all factor values in `x` are considered as potential outcomes.
- **con**: Numeric scalar between 0 and 1 to set the minimum consistency threshold every minimally sufficient condition (msc), atomic solution formula (asf), and complex solution formula (csf) must satisfy. (See also the argument con.msc below).
- **cov**: Numeric scalar between 0 and 1 to set the minimum coverage threshold every asf and csf must satisfy.
- **con.msc**: Numeric scalar between 0 and 1 to set the minimum consistency threshold every msc must satisfy. Overrides con for msc and, thereby, allows for imposing a consistency threshold on msc that differs from the threshold con imposes on asf and csf. Defaults to con.
maxstep  Vector of three integers; the first specifies the maximum number of conjuncts in each disjunct of an asf, the second specifies the maximum number of disjuncts in an asf, the third specifies the maximum complexity of an asf. The complexity of an asf is the total number of exogenous factor values in the asf. Default: c(3,4,10).

inus.only Logical; if TRUE, only disjunctive normal forms that are free of redundancies are retained as asf (see also is.inus). Defaults to only.minimal.msc && only.minimal.asf.

only.minimal.msc Logical; if TRUE (the default), only minimal conjunctions are retained as msc. If FALSE, sufficient conjunctions are not required to be minimal.

only.minimal.asf Logical; if TRUE (the default), only minimal disjunctions are retained as asf. If FALSE, necessary disjunctions are not required to be minimal.

maxSol Maximum number of asf calculated.

suff.only Logical; if TRUE, the function only searches for msc and not for asf and csf.

notcols Character vector of factors to be negated in x. If notcols = "all", all factors in x are negated.

rm.const.factors, rm.dup.factors Logical; if TRUE (default), factors with constant values are removed and all but the first of a set of duplicated factors are removed. These parameters are passed to configTable.

what Character string specifying what to print; "t" for the configuration table, "m" for msc, "a" for asf, "c" for csf, and "all" for all. Defaults to "ac" if suff.only = FALSE, and to "m" otherwise.

cutoff Minimum membership score required for a factor to count as instantiated in the data and to be integrated in the analysis. Value in the unit interval [0,1]. The default cutoff is 0.5. Only meaningful if type = "fs".

border Character vector specifying whether factors with membership scores equal to cutoff are rounded up ("up"), rounded down ("down") or dropped from the analysis ("drop"). Only meaningful if type = "fs".

details Either TRUE/FALSE, or a character vector with possible elements "exhaustiveness", "faithfulness", "coherence", "redundant", "cyclic". The strings can also be abbreviated, e.g. "e" or "exh" for "exhaustiveness", etc.

acyclic.only Logical; if TRUE, csf featuring a cyclic substructure are not returned. FALSE by default.

cycle.type Character string specifying what type of cycles to be detected: "factor" (the default) or "value" (cf. cyclic).

verbose Logical; if TRUE, some details on the csf building process are printed. FALSE by default.

digits Number of digits to print in consistency, coverage, exhaustiveness, faithfulness, and coherence scores.

nsolutions Maximum number of msc, asf, and csf to print. Alternatively, nsolutions = "all" will print all solutions.
show.cases Logical; if TRUE, the configTable’s attribute “cases” is printed. See print.configTable

In print.cna: arguments passed to other print-methods.

Details

The first input x of the cna function is a data frame or a configuration table. To ensure that no misinterpretations of returned asf and csf can occur, users are advised to use only upper case letters as factor (column) names. Column names may contain numbers, but the first sign in a column name must be a letter. Only ASCII signs should be used for column and row names.

The argument type allows for specifying the type of data x contains. As of package version 3.2, that argument has the default value “auto” inducing automatic detection of the data type. But the user can still manually set the data type. Data that feature factors taking values 1 or 0 only are called crisp-set, which can be indicated by type = “cs”. If the data contain at least one factor that takes more than two values, e.g. \{1,2,3\}, the data count as multi-value: type = "mv". Data featuring at least one factor taking real values from the interval [0,1] count as fuzzy-set: type = “fs”. (Note that mixing multi-value and fuzzy-set factors in one analysis is not (currently) supported).

A data frame or configuration table x is the only mandatory input of the cna function. In particular, cna does not need an input specifying which factor(s) in x are endogenous, it tries to infer that from the data. But if it is known prior to the analysis what factors have values that can figure as outcomes, an outcome specification can be given to cna via the argument outcome, which takes as input a character vector identifying one or several factor values as potential outcome(s). In case of “cs” and “fs” data, factor values are expressed by upper and lower cases (e.g. outcome = c("A","b")), in the “mv” case, they are expressed by the “factor=value” notation (e.g. outcome = c("A=1","B=3")). Defaults to outcome = TRUE, which means that all factor values in x are potential outcomes.

When the data x contain multiple potential outcomes, it may moreover be known, prior to the analysis, that these outcomes have a certain causal ordering, meaning that some of them are causally upstream of the others. Such information can be given to cna by means of the argument ordering, which takes as input a character vector identifying one or several factor values as potential outcome(s). In case of “cs” and “fs” data, factor values are expressed by upper and lower cases (e.g. outcome = c("A","b")), in the “mv” case, they are expressed by the “factor=value” notation (e.g. outcome = c("A=1","B=3")). Defaults to outcome = TRUE, which means that all factor values in x are potential outcomes.

The argument strict determines whether the elements of one level in an ordering can be causally related or not. For example, if ordering = "A,B < C" and strict = TRUE, then A and B—which are on the same level of the ordering—are excluded to be causally related and cna skips corresponding tests. By contrast, if ordering = "A,B < C" and strict = FALSE, then cna also searches for dependencies among A and B. The default is strict = FALSE.

If no outcomes are specified and no causal ordering is provided, all factor values in x are treated as potential outcomes; more specifically, in case of “cs” and “fs” data, cna tests for all factors whether their presence (i.e. them taking the value 1) can be modeled as an outcome, and in case of “mv” data, cna tests for all factors whether any of their possible values can be modeled as an outcome. That is done by searching for redundancy-free Boolean functions (in disjunctive normal
form) that account for the behavior of an outcome in accordance with cna’s core model fit parameters of consistency and coverage (for details see the cna package vignette or Ragin 2006). First, cna identifies all minimally sufficient conditions (msc) that meet the threshold given by the consistency threshold con.msc (resp. con, if con.msc = con) for each potential outcome in x. Then, these msc are disjunctively combined to minimally necessary conditions that meet the coverage threshold given by cov such that the whole disjunction meets the solution consistency threshold given by con. The resulting expressions are the atomic solution formulas (asf) for every factor value that can be modeled as outcome. The default value for con.msc, con, and cov is 1.

The cna function builds its models in four stages using a bottom-up search algorithm (see Baumgartner and Ambuehl 2020).

**First stage** On the basis of outcome and ordering, the algorithm builds a set of potential outcomes O from the factors in x.

**Second stage** The algorithm checks whether single factor values, e.g. A, b, C, (where "A" stands for "A=1" and "b" for "B=0") or D=3, E=2, etc., (whose membership scores, in case of "fs" data, meet cutoff in at least one case) are sufficient for a potential outcome in O (where a factor value counts as sufficient iff it meets the threshold given by con.msc). Next, conjuncts of two factor values, e.g. A*b, A*C, D=3*E=2 etc., (whose membership scores, in case of "fs" data, meet cutoff in at least one case) are tested for sufficiency. Then, conjuncts of three factors, and so on. Whenever a conjunction (or a single factor value) is found to be sufficient, all supersets of that conjunction contain redundancies and are, thus, not considered for the further analysis. The result is a set of msc for every potential outcome in O. To recover certain target structures in cases of noisy data, it may be useful to allow cna to also consider sufficient conditions for further analysis that are not minimal. This can be accomplished by setting only.minimal.msc to FALSE. A concrete example illustrating the utility of only.minimal.msc is provided in the “Examples” section below. (The ordinary user is advised not to change the default value of this argument.)

**Third stage** Minimally necessary disjunctions are built for each potential outcome in O by first testing whether single msc are necessary, then disjunctions of two msc, then of three, etc. (where a disjunction of msc counts as necessary iff it meets the threshold given by cov). Whenever a disjunction of msc (or a single msc) is found to be necessary, all supersets of that disjunction contain redundancies and are, thus, excluded from the further analysis. Finally, all and only those disjunctions of msc that meet both cov and con are issued as redundancy-free atomic solution formulas (asf). To recover certain target structures in cases of noisy data, it may be useful to allow cna to also consider necessary conditions for further analysis that are not minimal. This can be accomplished by setting only.minimal.asf to FALSE, in which case all disjunctions of msc reaching the con and cov thresholds will be returned. (The ordinary user is advised not to change the default value of this argument.)

As the combinatorial search space for asf is potentially too large to be exhaustively scanned in reasonable time, the argument maxstep allows for setting an upper bound for the complexity of the generated asf. maxstep takes a vector of three integers c(i,j,k) as input, entailing that the generated asf have maximally j disjuncts with maximally i conjuncts each and a total of maximally k factor values (k is the maximal complexity). The default is maxstep = c(3,4,10).

Note that when the data feature noise due to uncontrolled background influences the default con and cov thresholds of 1 will often not yield any asf. In such cases, con and cov may be set to suitable values in the interval [0.7, 1]. con and cov should neither be set too high, in order to avoid overfitting, nor too low, in order to avoid underfitting. The overfitting danger
is severe in causal modeling with CNA (and configurational causal modeling more generally). For a discussion of this problem see Parkkinen and Baumgartner (2021), who also introduce a procedure for robustness assessment that explores all threshold settings in a given interval—in an attempt to reduce both over- and underfitting. See also the R package frscore.

**Fourth stage** If cna finds asf, it builds complex solution formulas (csf) from those asf. This is done in a stepwise manner as follows. First, all logically possible conjunctions featuring one asf of every outcome are built. Second, if inus.only = TRUE, the solutions resulting from step 1 are freed of structural redundancies (cf. Baumgartner and Falk 2019), and tautologous and contradictory solutions as well as solutions with partial structural redundancies and constant factors are eliminated (cf. is.inus). Third, if acyclic.only = TRUE, solutions with cyclic substructures are eliminated. Fourth, for those solutions that were modified in the previous steps, consistency and coverage are re-calculated and solutions that no longer reach con or cov are eliminated. The remaining solutions are returned as csf. (See also csf.)

The default output of cna lists asf and csf, ordered by complexity and the product of consistency and coverage. It provides the consistency and coverage scores of each solution, a complexity score, which corresponds to the number of exogenous factor values in a solution, and a column “inus” indicating whether a solution has INUS form, meaning whether it is redundancy-free as required by the INUS-theory of causation (Mackie 1974, ch. 3; Baumgartner and Falk 2019). If inus.only = TRUE, all solutions automatically have INUS form, but if only.minimal.msc or only.minimal.asf are set to FALSE, non-INUS solutions may also be returned.

Apart from the standard solution attributes, cna can calculate a number of further solution attributes: exhaustiveness, faithfulness, coherence, redundant, and cyclic all of which are recovered by setting details to its non-default value TRUE or to a character vector specifying the attributes to be calculated. These attributes require explication (see also vignette("cna")):

- exhaustiveness and faithfulness are two measures of model fit that quantify the degree of correspondence between the configurations that are, in principle, compatible with a solution and the configurations contained in the data from which that solution is derived.
  - exhaustiveness amounts to the ratio of the number of configurations in the data that are compatible with a solution to the number of configurations in total that are compatible with a solution.
  - faithfulness amounts to the ratio of the number of configurations in the data that are compatible with a solution to the total number of configurations in the data.

- coherence measures the degree to which the asf combined in a csf cohere, i.e. are instantiated together in the data rather than independently of one another. For more details see coherence.

- redundant determines whether a csf contains structurally redundant proper parts. A csf with redundant = TRUE should not be causally interpreted. If inus.only = TRUE, all csf are free of structural redundancies. For more details see redundant.

- cyclic determines whether a csf contains a cyclic substructure. For more details see cyclic.

The argument notcols is used to calculate asf and csf for negative outcomes in data of type "cs" and "fs" (in "mv" data notcols has no meaningful interpretation and, correspondingly, issues an error message). If notcols = "all", all factors in x are negated, i.e. their membership scores i are replaced by 1−i. If notcols is given a character vector of factors in x, only the factors in that vector are negated. For example, notcols = c("A", "B") determines that only factors A and B are negated. The default is no negations, i.e. notcols = NULL.
suff.only is applicable whenever a complete cna analysis cannot be performed for reasons of computational complexity. In such a case, suff.only = TRUE forces cna to stop the analysis after the identification of msc, which will normally yield results even in cases when a complete analysis does not terminate. In that manner, it is possible to shed at least some light on the dependencies among the factors in x, in spite of an incomputable solution space.

rm.const.factors and rm.dup.factors are used to determine the handling of constant factors, i.e. factors with constant values in all cases (rows) in x, and of duplicated factors, i.e. factors that take identical value distributions in all cases in x. If rm.const.factors = TRUE, which is the default value, constant factors are removed from the data prior to the analysis, and if rm.dup.factors = TRUE (the default) all but the first of a set of duplicated factors are removed. From the perspective of configurational causal modeling, factors with constant values in all cases can neither be modeled as causes nor as outcomes; therefore, they can be removed prior to the analysis. Factors that take identical values in all cases cannot be distinguished configurationally, meaning they are one and the same factor as far as configurational causal modeling is concerned. Therefore, only one factor of a set of duplicated factors is standardly retained by cna.

The argument what can be specified both for the cna and the print() function. It regulates what items of the output of cna are printed. If what is given the value “t”, the configuration table is printed; if it is given an “m”, the msc are printed; if it is given an “a”, the asf are printed; if it is given a “c”, the csf are printed. what = "all" or what = "tmac" determine that all output items are printed. Note that what has no effect on the computations that are performed when executing cna; it only determines how the result is printed. The default output of cna is what = "ac". It first returns an implemented ordering or outcome specification. Second, the top 5 asf and, third, the top 5 csf are reported, along with an indication of how many solutions in total exist. To print all msc, asf, and csf, the corresponding functions in condTbl should be used. In case of suff.only = TRUE, what defaults to "m". msc are printed with an attribute minimal specifying whether a sufficient condition is minimal as required by the INUS-theory of causation. If inus.only = TRUE, all msc are minimal by default.

cna only includes factor configurations in the analysis that are actually instantiated in the data. The argument cutoff determines the minimum membership score required for a factor or a combination of factors to count as instantiated. It takes values in the unit interval [0,1] with a default of 0.5. border specifies whether configurations with membership scores equal to cutoff are rounded up (border = "up"), rounded down (border = "down"), which is the default, or dropped from the analysis (border = "drop").

The arguments digits, nsolutions, and show.cases apply to the print() method, which takes an object of class “cna” as first input. digits determines how many digits of consistency, coverage, coherence, exhaustiveness, and faithfulness scores are printed, while nsolutions fixes the number of conditions and solutions to print. nsolutions applies separately to minimally sufficient conditions, atomic solution formulas, and complex solution formulas. nsolutions = "all" recovers all minimally sufficient conditions, atomic and complex solution formulas. show.cases is applicable if the what argument is given the value “t". In that case, show.cases = TRUE yields a configuration table featuring a “cases” column, which assigns cases to configurations.

The option “spaces” controls how the conditions are rendered. The current setting is queried by typing getOption("spaces"). The option specifies characters that will be printed with a space before and after them. The default is c("<->", "->", "+-"). A more compact output is obtained with option(spaces = NULL).
cna

Value

cna returns an object of class “cna”, which amounts to a list with the following elements:

- **call**: the executed function call
- **x**: the processed data frame or configuration table
- **configTable**: the object of class “configTable”, as input to cna
- **configTable_out**: the object of class “configTable”, after modification according to notcols
- **solution**: the solution object, which itself is composed of lists exhibiting msc, asf, and csf for all factors in x
- **what**: the values given to the what argument
- **details**: the calculated solution attributes
  - ...: plus additional list elements reporting the values given to the parameters con, cov, con.msc, inus.only, acyclic.only, and cycle.type.

Thiem, Alrik: testing

Note

In the first example described below (in Examples), the two resulting complex solution formulas represent a common cause structure and a causal chain, respectively. The common cause structure is graphically depicted in figure (a) below, the causal chain in figure (b).

# The previous function call yields a total of 14 asf and csf, only 5 of which are
# printed in the default output. Here is how to extract all 14 asf and csf.
asf(cna.pban)
csf(cna.pban)

# [Note that all of these 14 causal models reach better consistency and
# coverage scores than the one model Hartmann & Kemmerzell (2010) present in their paper,
# which they generated using the TOSMANA software, version 1.3.
# T=0 + T=1 + C=2 + T=1*V=0 + T=2*V=0 <-> PB=1]
condTbl("T=0 + T=1 + C=2 + T=1*V=0 + T=2*V=0 <-> PB = 1", d.pban)

# Extract all minimally sufficient conditions.
msc(cna.pban)

# Alternatively, all msc, asf, and csf can be recovered by means of the nsolutions
# argument of the print function.
print(cna.pban, nsolutions = "all")

# Print the configuration table with the "cases" column.
print(cna.pban, what = "t", show.cases = TRUE)

# Build solution formulas with maximally 4 disjuncts.
cna(d.pban, outcome = "PB=1", cov = .95, maxstep = c(4, 4, 10))

# Only print 2 digits of consistency and coverage scores.
print(cna.pban, digits = 2)

# Build all but print only two msc for each factor and two asf and csf.
print(cna(d.pban, outcome = "PB=1", cov = .95,
         maxstep = c(6, 6, 10), what = "all"), nsolutions = 2)

# Lowering the consistency instead of the coverage threshold yields further models with
# excellent fit scores; print only asf.
cna(d.pban, outcome = "PB=1", con = .93, what = "a", maxstep = c(6, 6, 10))

# Specifying an outcome is unnecessary for d.pban. PB=1 is the only
# factor value in those data that could possibly be an outcome.
cna(d.pban, cov = .95, maxstep = c(6, 6, 10))

# Fuzzy-set data from Basurto (2013) on autonomy of biodiversity institutions in Costa Rica
# ---------------------------------------------------------------------------------------
# Basurto investigates two outcomes: emergence of local autonomy and endurance thereof. The
# data for the first outcome are contained in rows 1-14 of d.autonomy, the data for the second
# outcome in rows 15-30. For each outcome, the author distinguishes between local ("EM",
# "SP", "CO"), national ("CI", "PO") and international ("RE", "CN", "DE") conditions. Here,
we first apply fsCNA to replicate the analysis for the local conditions of the endurance of 
local autonomy.

```r
dat1 <- d.autonomy[15:30, c("AU","EM","SP","CO")]
cna(dat1, ordering = "AU", strict = TRUE, con = .9, cov = .9)
```

The fsCNA model has significantly better consistency (and equal coverage) scores than the 
model presented by Basurto (p. 580): SP*EM + CO <-> AU, which he generated using the 
fs/QCA software.

```r
condition("SP*EM + CO <-> AU", dat1) # both EM and CO are redundant to account for AU
```

If we allow for dependencies among the conditions by setting strict = FALSE, CNA reveals 
that SP is a common cause of both AU and EM.

```r
cna(dat1, ordering = "AU", strict = FALSE, con = .9, cov = .9)
```

Here is the analysis for the international conditions of autonomy endurance, which 
yields the same model as the one presented by Basurto (plus one model Basurto does not mention).

```r
dat2 <- d.autonomy[15:30, c("AU","RE", "CN", "DE")]
cna(dat2, ordering = "AU", con = .9, con.msc = .85, cov = .85)
```

But there are other models (here printed with all solution attributes) 
that fare equally well.

```r
cna(dat2, ordering = "AU", con = .85, cov = .9, details = TRUE)
```

Finally, here is an analysis of the whole dataset, showing that across the whole period 
1986-2006, the best causal model of local autonomy (AU) renders that outcome dependent 
only on local direct spending (SP).

```r
cna(d.autonomy, outcome = "AU", con = .85, cv = .9, 
       maxstep = c(5, 5, 11), details = TRUE)
```

Also build non-INUS solutions.

```r
asf(cna(d.autonomy, outcome = "AU", con = .85, cov = .9, 
       maxstep = c(5, 5, 11), details = TRUE, inus.only = FALSE))
```

High-dimensional data

As of package version 3.1, cna's handling of data with more than 20 factors 
has been improved. Here's an analysis of the data d.highdim with 50 factors, massive 
fragmentation, and 20% noise. (Takes about 15 seconds to compute.)

```r
head(d.highdim)
cna(d.highdim, outcome = c("V13", "V11"), con = .8, cov = .8)
```

By lowering maxstep, computation time can be reduced to less than 1 second 
(at the cost of an incomplete solution).

```r
cna(d.highdim, outcome = c("V13", "V11"), con = .8, cov = .8, 
       maxstep = c(2,3,10))
```

coherence

Calculate the coherence of complex solution formulas

Description

Calculates the coherence measure of complex solution formulas (csf).

Usage

coherence(x, ...)

## Default S3 method:

coherence(x, ct, type, ..., tt)

Arguments

x Character vector specifying an asf or csf.
ct Data frame or configTable.
type Character vector specifying the type of x: "auto" (automatic detection; default), "cs" (crisp-set), "mv" (multi-value), or "fs" (fuzzy-set).
... Arguments passed to methods.
tt Argument tt is deprecated in coherence(); use x instead.

details

Coherence is a measure for model fit that is custom-built for complex solution formulas (csf). It measures the degree to which the atomic solution formulas (asf) combined in a csf cohere, i.e. are instantiated together in x rather than independently of one another. More concretely, coherence is the ratio of the number of cases satisfying all asf contained in a csf to the number of cases satisfying at least one asf in the csf. For example, if the csf contains the three asf asf1, asf2, asf3, coherence amounts to |asf1 * asf2 * asf3| / |asf1 + asf2 + asf3|, where |...| expresses the cardinality of the set of cases in x instantiating the corresponding expression. For asf, coherence returns 1. For boolean conditions (see condition), the coherence measure is not defined and coherence hence returns NA. For multiple csf that do not have a factor in common, coherence returns the minimum of the separate coherence scores.

Value

Numeric vector of coherence values to which cond is appended as a "names" attribute. If cond is a csf "asf1*asf2*asf3" composed of asf that do not have a factor in common, the csf is rendered with commas in the "names" attribute: "asf1, asf2, asf3".

Examples

# Perfect coherence.
dat1 <- selectCases("(A*b <-> C)*(C + D <-> E)")
coherence("(A*b <-> C)*(C + D <-> E)", dat1)
csf(cna(dat1, details = "coherence"))

# Non-perfect coherence.
dat2 <- selectCases("(a*B <-> C)*(C + D <-> E)*(F*g <-> H)")
dat3 <- rbind(ct2df(dat2), c(0,1,0,1,1,0,1))
coherence("(a*B <-> C)*(C + D <-> E)*(F*g <-> H)", dat3)
csf(cna(dat3, con = .88, details = "coherence"))

condition

Uncover relevant properties of msc, asf, and csf in a data frame or configTable

Description

The condition function provides assistance to inspect the properties of msc, asf, and csf (as returned by cna) in a data frame or configTable, but also of any other Boolean function. condition reveals which configurations and cases instantiate a given msc, asf, or csf and lists consistency and coverage scores.

Usage

condition(x, ...)

## Default S3 method:
condition(x, ct, type, add.data = FALSE,
  force.bool = FALSE, rm.parentheses = FALSE, ..., tt)

## S3 method for class 'condTbl'
condition(x, ct, ...)

## S3 method for class 'condList'
print(x, ...)

## S3 method for class 'condList'
summary(object, ...)

## S3 method for class 'cond'
print(x, digits = 3, print.table = TRUE,
  show.cases = NULL, add.data = NULL, ...)

group.by.outcome(condlst, cases = TRUE)

Arguments

x

Character vector specifying a Boolean expression as "A + B*C -> D", where "A", "B", "C", "D" are column names in ct.
ct  Data frame or configTable (see configTable).

type  Character vector specifying the type of x: "auto" (automatic detection; default), "cs" (crisp-set), "mv" (multi-value), or "fs" (fuzzy-set).

add.data  Logical; if TRUE, ct is attached to the output. Alternatively, ct can be requested by the add.data argument in print.cond.

force.bool  Logical; if TRUE, x is interpreted as a mere Boolean function, not as a causal model.

rm.parentheses  Logical; if TRUE, parentheses around x are removed prior to evaluation.

digits  Number of digits to print in consistency and coverage scores.

print.table  Logical; if TRUE, the table assigning configurations and cases to conditions is printed.

show.cases  In print.cond: logical; if TRUE, the attribute “cases” of the configTable is printed. Same default behavior as in print.configTable.

object  Object of class “condList”, as returned by condition().

condlst  List of objects, each of them of class “cond”, as returned by condition().

cases  Logical; if TRUE, the returned data frame has a column named “cases”.

...  Arguments passed to methods.

tt  Argument tt is deprecated in condition(); use ct instead.

Details

Depending on the processed data frame or configTable, the solutions output by cna are often ambiguous; that is, it can happen that many solution formulas fit the data equally well. In such cases, the data alone are insufficient to single out one solution. While cna simply lists the possible solutions, the condition function is intended to provide assistance in comparing different minimally sufficient conditions (msc), atomic solution formulas (asf), and complex solution formulas (csf) in order to have a better basis for selecting among them.

Most importantly, the output of the condition function highlights in which configurations and cases in the data an msc, asf, and csf is instantiated. Thus, if the user has independent causal knowledge about particular configurations or cases, the information received from condition may be helpful in selecting the solutions that are consistent with that knowledge. Moreover, the condition function allows for directly contrasting consistency and coverage scores or frequencies of different conditions contained in returned asf.

The condition function is independent of cna. That is, any msc, asf, or csf—irrespective of whether they are output by cna—can be given as input to condition. Even Boolean expressions that do not have the syntax of CNA solution formulas can be passed to condition.

The first required input x of condition is a character vector consisting of Boolean formulas composed of factor names that are column names of ct, which is the second required input. ct can be a configTable or a data frame. If ct is a data frame and the type argument has its default value "auto", condition first determines the data type and then converts the data frame to a configTable. The data type can also be manually specified by giving the type argument one of the values "cs", "mv", or "fs".

Conjunction can be expressed by "\&" or "&", disjunction by "\|" or "|", negation can be expressed by "-" or "!" or, in case of crisp-set or fuzzy-set data, by changing upper case into lower case letters and vice versa, implication by "\rightarrow", and equivalence by "\leftrightarrow". Examples are
The types of conditions are distinguished:

- The type **boolean** comprises Boolean expressions that do not have the syntactic form of causal models, meaning the corresponding character strings in the argument do not have an “-\(\rightarrow\)” or “\(<\sim\spadesuit\rangle\)” as main operator. Examples: "\(A*B + C\)” or "\(-(A*B + -(C+d))\)”. The expression is evaluated and written into a data frame with one column. Frequency is attached to this data frame as an attribute.

- The type **atomic** comprises expressions that have the syntactic form of atomic causal models, i.e. asf, meaning the corresponding character strings in the argument have an “-\(\rightarrow\)” or “\(<\sim\rightarrow\)” as main operator. Examples: "\(A*B + C \rightarrow D\)” or "\(A*B + C <-> D\)”. The expressions on both sides of “\(-\rightarrow\)” and “\(<\sim\rightarrow\)” are evaluated and written into a data frame with two columns. Consistency and coverage are attached to these data frames as attributes.

- The type **complex** represents complex causal models, i.e. csf. Example: "\((A*B + a*b <-> C)*(C*d + c*D <-> E)\)”. Each component must be a causal model of type **atomic**. These components are evaluated separately and the results stored in a list. Consistency and coverage of the complex expression are then attached to this list.

The types of the character strings in the input are automatically discerned and thus do not need be specified by the user.

If `force.bool = TRUE`, expressions with “-\(\rightarrow\)” or “\(<\sim\rightarrow\)” are treated as type **boolean**, i.e. only their frequencies are calculated. Enclosing a character string representing a causal model in parentheses has the same effect as specifying `force.bool = TRUE`. `rm.parentheses = TRUE` removes parentheses around the expression prior to evaluation, and thus has the reverse effect of setting `force.bool = TRUE`.

If `add.data = TRUE`, `ct` is appended to the output such as to facilitate the analysis and evaluation of a model on the case level.

The `digits` argument of the `print` function determines how many digits of consistency and coverage scores are printed. If `print.table = FALSE`, the table assigning conditions to configurations and cases is omitted, i.e. only frequencies or consistency and coverage scores are returned. `row.names = TRUE` also lists the row names in `ct`. If rows in a `ct` are instantiated by many cases, those cases are not printed by default. They can be recovered by `show.cases = TRUE`.

`group.by.outcome` takes a `condlist` as input, i.e. a list of “cond” objects, as it is returned by condition, and combines the entries in that lists into a data frame with a larger number of columns. The additional attributes (consistencies etc.) are thereby removed.

**Value**

`condition` returns a list of objects, each of them corresponding to one element of the input vector `x`. The list has a class attribute “condList”, the list elements (i.e., the individual conditions) are of class “cond” and have a more specific class label “booleanCond”, “atomicCond” or “complexCond”, according to the condition type. The components of class “booleanCond” or “atomicCond” are amended data frames, those of class “complexCond” are lists of amended data frames.

`group.by.outcome` returns a list of data frames, one data frame for each factor appearing as an outcome in `condlist`. 
print and summary methods

print.condList essentially executes print.cond successively for each list element/condition. All arguments in print.condList are thereby passed to print.cond, i.e. digits, print.table, show.cases, add.data can also be specified when printing the complete list of conditions.

The summary method for class “condList” is identical to printing with print.table = FALSE.

The option “spaces” controls how the conditions are rendered in certain contexts. The current setting is queried by typing getOption("spaces"). The option specifies characters that will be printed with a space before and after them. The default is c("<->","->","+"). A more compact output is obtained with option(spaces = NULL).

condTbl

condTbl

Description

Given a solution object x produced by cna, msc(x) extracts all minimally sufficient conditions, asf(x) all atomic solution formulas, and csf(x, n.init) builds approximately n.init complex solution formulas. All solution attributes (details) that are saved in x are recovered as well. The three functions return a data frame with the additional class attribute condTbl.

as.condTbl reshapes the output produced by condition in such a way as to make it identical to the output returned by msc, asf, and csf.

condTbl executes condition and returns a concise summary table featuring consistencies and coverages.
Usage

msc(x, details = x$details)
asf(x, details = x$details, warn_details = TRUE)
csf(x, n.init = 1000, details = x$details,
    asfx = asf(x, details, warn_details = FALSE),
    inus.only = x$inus.only, minimalizeCsf = inus.only,
    acyclic.only = x$acyclic.only, cycle.type = x$cycle.type,
    verbose = FALSE)

## S3 method for class 'condTbl'
print(x, n = 20, digits = 3, quote = FALSE, row.names = TRUE, ...)

condTbl(...)
as.condTbl(x, ...)

Arguments

x Object of class “cna”. In as.condTbl, x is a list of evaluated conditions as returned by condition. In print, x is an object returned by msc, asf, or csf.
details Either TRUE/FALSE or a character vector specifying which solution attributes to print (see cna). Note that msc and asf can only display attributes that are saved in x, i.e. those that have been requested in the details argument within the call of cna.
warn_details Logical; if TRUE, a warning is issued when some attribute requested in details is not available in x (parameter for internal use).
n.init Integer capping the amount of initial asf combinations. Default at 1000. Serves to control the computational complexity of the csf building process.
asfx Object of class “condTbl” produced by the asf function.
inus.only Logical; if TRUE, csf are freed of structural redundancies and only csf not featuring partial structural redundancies are retained (see the fourth stage of cna’s search algorithm). Defaults to x$inus.only.
minimalizeCsf Logical; if TRUE, csf are freed of structural redundancies.
acyclic.only Logical; if TRUE, csf featuring a cyclic substructure are not returned. FALSE by default.
cycle.type Character string specifying what type of cycles to be detected: "factor" (the default) or "value" (cf. cyclic).
verbose Logical; if TRUE, some details on the csf building process are printed. FALSE by default.
n Maximal number of msc, asf, or csf to be printed.
digits Number of digits to print in consistency, coverage, exhaustiveness, faithfulness, and coherence scores.
quote, row.names As in print.data.frame.
...
All arguments in condTbl are passed on to condition.
Details

Depending on the processed data, the solutions (models) output by \texttt{cna} are often ambiguous, to the effect that many atomic and complex solutions fit the data equally well. To facilitate the inspection of the \texttt{cna} output, however, the latter standardly returns only 5 minimally sufficient conditions (msc), 5 atomic solution formulas (asf), and 5 complex solution formulas (csf) for each outcome. \texttt{msc} can be used to extract \textit{all} msc from an object \texttt{x} of class “cna”, \texttt{asf} to extract \textit{all} asf, and \texttt{csf} to build approximately \texttt{n.init} csf from the asf stored in \texttt{x}. All solution attributes (details) that are saved in \texttt{x} are recovered as well. The outputs of msc, asf, and csf can be further processed by the \texttt{condition} function.

While \texttt{msc} and \texttt{asf} merely extract information stored in \texttt{x}, \texttt{csf} builds csf from the inventory of asf recovered at the end of the third stage of the \texttt{cna} algorithm. That is, the \texttt{csf} function implements the fourth stage of that algorithm. It proceeds in a stepwise manner as follows.

1. \texttt{n.init} possible conjunctions featuring one asf of every outcome are built.
2. If \texttt{inus.only = TRUE} or \texttt{minimalizeCsf = TRUE}, the solutions resulting from step 1 are freed of structural redundancies (cf. Baumgartner and Falk 2019).
3. If \texttt{inus.only = TRUE}, tautologous and contradictory solutions as well as solutions with partial structural redundancies and constant factors are eliminated. [If \texttt{inus.only = FALSE} and \texttt{minimalizeCsf = TRUE}, only structural redundancies are eliminated, meaning only step 2, but not step 3, is executed.]
4. If \texttt{acyclic.only = TRUE}, solutions with cyclic substructures are eliminated.
5. For those solutions that were modified in the previous steps, consistency and coverage are re-calculated and solutions that no longer reach \texttt{con} or \texttt{cov} are eliminated.
6. The remaining solutions are returned as csf, ordered by complexity and the product of consistency and coverage.

The argument \texttt{digits} applies to the \texttt{print} method. It determines how many digits of consistency, coverage, exhaustiveness, faithfulness, and coherence scores are printed. The default value is 3.

The function \texttt{as.condTbl} takes a list of objects of class “cond” that are returned by the \texttt{condition} function as input, and reshapes these objects in such a way as to make them identical to the output returned by \texttt{msc}, \texttt{asf}, and \texttt{csf}.

\texttt{condTbl}(...) is identical with \texttt{as.condTbl(condition(...)).}

Value

\texttt{msc}, \texttt{asf}, \texttt{csf}, and \texttt{as.condTbl} return objects of class “condTbl”, a \texttt{data.frame} which features the following components:

- \texttt{outcome}: the outcomes
- \texttt{condition}: the relevant conditions or solutions
- \texttt{consistency}: the consistency scores
- \texttt{coverage}: the coverage scores
- \texttt{complexity}: the complexity scores
- \texttt{inus}: whether the solutions have INUS form
- \texttt{exhaustiveness}: the exhaustiveness scores
- \texttt{faithfulness}: the faithfulness scores
- \texttt{coherence}: the coherence scores
redundant: whether the csf contain redundant proper parts

cyclic: whether the csf contain cyclic substructures

The latter five measures are optional and will be appended to the table according to the setting of the argument details.

**configTable**  
Assemble cases with identical configurations in a configuration table

---

**Description**

The `configTable` function assembles cases with identical configurations from a crisp-set, multi-value, or fuzzy-set data frame in a table called a **configuration table**.

**Usage**

```r
configTable(x, type = c("auto", "cs", "mv", "fs"), frequency = NULL,
           case.cutoff = 0, rm.dup.factors = TRUE, rm.const.factors = TRUE,
           .cases = NULL, verbose = TRUE)
```

```r
## S3 method for class 'configTable'
print(x, show.cases = NULL, ...)
```

**Arguments**

- **x** Data frame or matrix.
- **type** Character vector specifying the type of `x`: "auto" (automatic detection; default), "cs" (crisp-set), "mv" (multi-value), or "fs" (fuzzy-set).
- **frequency** Numeric vector of length `nrow(x)`. All elements must be non-negative.
- **case.cutoff** Minimum number of occurrences (cases) of a configuration in `x`. Configurations with fewer than `case.cutoff` occurrences (cases) are not included in the configuration table.
- **rm.dup.factors** Logical; if TRUE, all but the first of a set of factors with identical values in `x` are removed.
- **rm.const.factors** Logical; if TRUE, factors with constant values in `x` are removed.
- **.cases** Optional character vector of length `nrow(x)` to set case labels (row names).
- **verbose** Logical; if TRUE, some messages on the configuration table are printed.
- **show.cases** Logical; if TRUE, the attribute "cases" is printed.
- **...** In `print.configTable`: arguments passed to `print.data.frame`. 
Details

The first input x of the configTable function is a data frame. To ensure that no misinterpretations of issued asf and csf can occur, users are advised to use only upper case letters as factor (column) names. Column names may contain numbers, but the first sign in a column name must be a letter. Only ASCII signs should be used for column and row names.

The configTable function merges multiple rows of x featuring the same configuration into one row, such that each row of the resulting table, which is called a configuration table, corresponds to one determinate configuration of the factors in x. The number of occurrences (cases) and an enumeration of the cases are saved as attributes ‘n’ and ‘cases’, respectively. The attribute “n” is always printed in the output of configTable, the attribute “cases” is printed if the argument show.cases is TRUE in the print method.

The argument type allows for manually specifying the type of data; it defaults to "auto", which induces automatic detection of the data type. "cs" stands for crisp-set data featuring factors that only take values 1 and 0; "mv" stands for multi-value data with factors that can take any non-negative integers as values; "fs" stands for fuzzy-set data comprising factors taking real values from the interval [0,1], which are interpreted as membership scores in fuzzy sets.

Instead of multiply listing identical configurations in x, the frequency argument can be used to indicate the frequency of each configuration in the data frame. frequency takes a numeric vector of length nrow(x) as value. For instance, configTable(x,frequency = c(3,4,2,3)) determines that the first configuration in x is featured in 3 cases, the second in 4, the third in 2, and the fourth in 3 cases.

The case.cutoff argument is used to determine that configurations are only included in the configuration table if they are instantiated at least as many times in x as the number assigned to case.cutoff. Or differently, configurations that are instantiated less than case.cutoff are excluded from the configuration table. For instance, configTable(x,case.cutoff = 3) entails that configurations with less than 3 cases are excluded.

rm.dup.factors and rm.const.factors allow for determining whether all but the first of a set of duplicated factors (i.e. factors with identical value distributions in x) are eliminated and whether constant factors (i.e. factors with constant values in all cases (rows) in x) are eliminated. From the perspective of configurational causal modeling, factors with constant values in all cases can neither be modeled as causes nor as outcomes; therefore, they can be removed prior to the analysis. Factors with identical value distributions cannot be distinguished configurationally, meaning they are one and the same factor as far as configurational causal modeling is concerned. Therefore, only one factor of a set of duplicated factors is standardly retained by configTable.

.cases can be used to set case labels (row names). It is a character vector of length nrow(x).

The row.names argument of the print function determines whether the case labels of x are printed or not. By default, row.names is TRUE unless the (comma-separated) list of the cases exceeds 20 characters in at least one row.

Value

An object of type “configTable”, i.e. a data.frame with additional attributes “type”, “n” and “cases”.

Note

For those users of cna that are familiar with Qualitative Comparative Analysis (QCA), it must be emphasized that a configuration table is a different type of object than a QCA truth table. While
a truth table is a list indicating whether a minterm (i.e. a configuration of all exogenous factors) is sufficient for the outcome or not, a configuration table is simply an integrated representation of the input data that lists all configurations in the data exactly once. A configuration table does not express relations of sufficiency.

cyclic
Detect cyclic substructures in complex solution formulas (csf)

**Description**

Given a character vector `x` specifying complex solution formula(s) (csf), `cyclic(x)` checks whether `x` contains cyclic substructures. The function can be used, for instance, to filter cyclic causal models out of `cna` solution objects (e.g. in order to reduce ambiguities).

**Usage**

```r
cyclic(x, cycle.type = c("factor", "value"), use.names = TRUE, verbose = FALSE)
```

**Arguments**

- `x` Character vector specifying one or several csf.
- `cycle.type` Character string specifying what type of cycles to be detected: "factor" (the default) or "value".
- `use.names` Logical; if TRUE, names are added to the result (see examples).
- `verbose` Logical; if TRUE, the checked causal paths are printed to the console.

**Details**

Detecting causal cycles is one of the most challenging tasks in causal data analysis—in all methodological traditions. In a nutshell, the reason is that factors in a cyclic structure are so highly interdependent that, even under optimal discovery conditions, the diversity of (observational) data tends to be too limited to draw informative conclusions about the data generating structure. In consequence, various methods (most notably, Bayes nets methods, cf. Spirtes et al. 2000) assume that analyzed data generating structures are acyclic.

`cna` outputs cyclic complex solution formulas (csf) if they fit the data. Typically, however, the causal modeling of configurational data that can be modeled in terms of cycles is massively ambiguous. Therefore, if there are independent reasons to assume that the data are not generated by a cyclic structure, the function `cyclic` can be used to reduce the ambiguities in a `cna` output by filtering out all csf with cyclic substructures.

A causal structure has a cyclic substructure if, and only if, it contains a directed causal path from at least one cause back to itself. The INUS-theory of causation spells this criterion out as follows: a csf `x` has a cyclic substructure if, and only if, `x` contains a sequence `<Z1, Z2, ...., Zn>` every element of which is an INUS condition of its successor and `Z1 = Zn`. Accordingly, the function `cyclic` searches for sequences `<Z1, Z2, ...., Zn>` of factors or factor values in a csf `x` such that (i) every `Zi` is contained...
in the antecedent (i.e. the left-hand side of "<->") of and atomic solution formula (asf) of Zi+1 in x, and (ii) Zn is identical to Z1. The function returns TRUE if, and only if, at least one such sequence (i.e. directed causal path) is contained in x.

The cycle.type argument controls whether the sequence <Z1, Z2....., Zn> is composed of factors (cycle.type = "factor") or factor values (cycle.type = "value"). To illustrate, if cycle.type = "factor", the following csf is considered cyclic: (A + B <-> C)*(c + D <-> A). The factor A (with value 1) appears in the antecedent of an asf of C (with value 1), and the factor C (with value 0) appears in the antecedent of an asf of A (with value 1). But if cycle.type = "value", that same csf does not pass as cyclic. Although the factor value 1 of A appears in the antecedent of an asf of the factor value 1 of C, that same value of C does not appear in the antecedent of an asf of A; rather, the value 0 of C appears in the antecedent of A.

If verbose = TRUE, the sequences (paths) tested for cyclicity are output to the console. Note that the search for cycles is stopped as soon as one cyclic sequence (path) has been detected. Accordingly, not all sequences (paths) contained in x may be output to the console.

Value

A logical vector: TRUE for a csf with at least one cyclic substructure, FALSE for a csf without any cyclic substructures.

References

Examples

# cna() infers two csf from the d.educate data, neither of which has a cyclic # substructure.

**d.autonomy**  
*Emergence and endurance of autonomy of biodiversity institutions in Costa Rica*

**Description**

This dataset is from Basurto (2013), who analyzes the causes of the emergence and endurance of autonomy among local institutions for biodiversity conservation in Costa Rica between 1986 and 2006.

**Usage**

`d.autonomy`

**Format**

The data frame contains 30 rows (cases), which are divided in two halves: rows 1 to 14 comprise data on the emergence of local autonomy between 1986 and 1998, rows 15 to 30 comprise data on
the endurance of local autonomy between 1998 and 2006. The data has the following 9 columns featuring fuzzy-set factors:

| . 1 | AU | local autonomy (ultimate outcome) |
| . 2 | EM | local communal involvement through direct employment |
| . 3 | SP | local direct spending |
| . 4 | CO | co-management with local or regional stakeholders |
| . 5 | CI | degree of influence of national civil service policies |
| . 6 | PO | national participation in policy-making |
| . 7 | RE | research-oriented partnerships |
| . 8 | CN | conservation-oriented partnerships |
| . 9 | DE | direct support by development organizations |

**d.educate**

*Artificial data on education levels and left-party strength*

**Description**

This artificial dataset of macro-sociological factors on high levels of education is from Baumgartner (2009).

**Usage**

d.educate

**Format**

The data frame contains 8 rows (cases) and the following 5 columns featuring Boolean factors taking values 1 and 0 only:

- [ , 1] U existence of strong unions
- [ , 2] D high level of disparity
- [ , 3] L existence of strong left parties
- [ , 4] G high gross national product
- [ , 5] E high level of education

**Source**

Artificial data with 50 factors and 1191 cases

Description

These crisp-set data are simulated from a presupposed data generating structure (i.e. a causal chain). They feature 20% noise and massive fragmentation (limited diversity). \texttt{d.highdim} is used to illustrate CNA's capacity to analyze high-dimensional data.

Usage

\texttt{d.highdim}

Format

The data frame contains 50 factors (columns), V1 to V50, and 1191 rows (cases). It was simulated from the following data generating structure:

\[(v_2 \times V_{10} + V_{18} \times V_{16} \times v_{15} < \rightarrow V_{13}) \times (V_2 \times v_{14} + V_3 \times v_{12} + V_{13} \times V_{19} < \rightarrow V_{11})\]

20% of the cases in \texttt{d.highdim} are incompatible with that structure, meaning they are affected by noise or measurement error. The fragmentation is massive, as there is a total of 281 trillion \(2^{48}\) configurations over the set \{V1,\ldots,V50\} that are compatible with that structure.

Source

d.highdim has been generated with the following code:

\begin{verbatim}
RNGversion("4.0.0")
set.seed(39)
m0 <- matrix(0,5000,50)
dat1 <- as.data.frame(apply(m0,c(1,2),function(x) sample(c(0,1),1)))
target <- "(v2*V10 + V18*V16*v15 <-> V13)*(V2*v14 + V3*v12 + V13*V19 <-> V11)"
dat2 <- ct2df(selectCases(target,dat1))
incomp.data <- dplyr::setdiff(dat1,dat2)

no.replace <- round(nrow(dat2)*0.2)
a <- dat2[sample(nrow(dat2),nrow(dat2)-no.replace,replace = FALSE),]
b <- some(incomp.data,no.replace)
d.highdim <- rbind(a,b)
head(d.highdim)
\end{verbatim}
Data on the impact of development interventions on water adequacy in Nepal

Description
This dataset is from Lam and Ostrom (2010), who analyze the effects of an irrigation experiment in Nepal.

Usage
d.irrigate

Format
The dataset contains 15 rows (cases) and the following 6 columns featuring Boolean factors taking values 1 and 0 only:

- A: continual assistance on infrastructure improvement
- R: existence of a set of formal rules for irrigation operation and maintenance
- F: existence of provisions of fines
- L: existence of consistent leadership
- C: existence of collective action among farmers for system maintenance
- W: persistent improvement in water adequacy at the tail end in winter

*d.women*  
*Data on high percentage of women's representation in parliaments of western countries*
Description

This dataset is from Krook (2010), who analyzes the causal conditions for high women’s representation in western-democratic parliaments.

Usage

d.women

Format

The data frame contains 22 rows (cases) and the following 6 columns featuring Boolean factors taking values 1 and 0 only:

- [.1] ES: existence of a PR electoral system
- [.2] QU: existence of quotas for women
- [.3] WS: existence of social-democratic welfare system
- [.4] WM: existence of autonomous women’s movement
- [.5] LP: strong left parties
- [.6] WNP: high women’s representation in parliament

Source

full.ct

Generate all logically possible value configurations of a given set of factors

Description

The function full.ct generates a configTable with all logically possible value configurations of the factors defined in the input x. It is more flexible than allCombs. x can be a configTable, a data frame, an integer, a list specifying the factors’ value ranges, or a character string expressing a condition featuring all admissible factor values.

Usage

full.ct(x, ...)

## Default S3 method:
full.ct(x, type = "auto", cond = NULL, ...)

## S3 method for class 'configTable'
full.ct(x, cond = NULL, ...)

## S3 method for class 'cti'
full.ct(x, cond = NULL, ...)
Arguments

- **x**: A configTable, a data frame, a matrix, an integer, a list specifying the factors’ value ranges, or a character vector featuring all admissible factor values (see the details and examples below).

- **type**: Character vector specifying the type of x: "auto" (automatic detection; default), "cs" (crisp-set), "mv" (multi-value), or "fs" (fuzzy-set). (Manual specification of the type only has an effect if x is a data frame or matrix.)

- **cond**: Optional character vector containing conditions in the syntax of msc, asf or csf. If it is not NULL, only factors appearing in cond are used.

- **...**: Further arguments passed to methods.

Details

full.ct generates all logically possible value configurations of the factors defined in x, which can either be a character vector or an integer or a list or a data frame or a matrix.

- If x is a character vector, it can be a condition of any of the three types of conditions, boolean, atomic or complex (see condition). x must contain at least one factor. Factor names and admissible values are guessed from the Boolean formulas. If x contains multi-value factors, only those values are considered admissible that are explicitly contained in x. Accordingly, in case of multi-value factors, full.ct should be given the relevant factor definitions by means of a list (see below).

- If x is an integer and <=26, the output will be a logically complete configuration table of type "cs" with x factors. The first x capital letters of the alphabet will be used as the names of the factors.

- If x is a list, x is expected to have named elements each of which provides the factor names with corresponding vectors enumerating their admissible values (i.e. their value ranges). These values must be non-negative integers.

- If x is a configTable, data frame, or matrix, colnames(x) are interpreted as factor names and the rows as enumerating the admissible values (i.e. as value ranges). If x is a data frame or a matrix, x is first converted to a configTable (the function configTable is called with type as specified in full.ct), and the configTable method of full.ct is then applied to the result. The configTable method uses all factors and factor values occurring in the configTable. If x is of type "fs", 0 and 1 are taken as the admissible values.

If not all factors specified in x are of interest but only those in a given msc, asf, or csf, full.ct can be correspondingly restricted via the argument cond. For instance, full.ct(d.educate, cond = "D + L <-> E") generates all logically possible value configurations of the factors in the set (D, L, E), even though d.educate contains further factors. The argument cond is primarily used internally to speed up the execution of various functions in case of high-dimensional data.

The main area of application of full.ct is data simulation in the context of inverse search trials benchmarking the output of cna (see examples below). While full.ct generates the space of all logically possible configurations of the factors in an analyzed factor set, selectCases selects those configurations from this space that are compatible with a given data generating causal structure (i.e. the ground truth), that is, it selects the empirically possible configurations.

The method for class "cti" is for internal use only.
Value

A configTable of type "cs" or "mv" with the full enumeration of combinations of the factor values.

(realData <- rbind(ct2df(fullData[sample(1:nrow(fullData), nrow(fragData)*0.1), ]),
                   fragData))
is.inus checks for each element of a character vector of disjunctive normal forms (DNFs) or expressions in the syntax of CNA solution formulas whether it has INUS form, meaning whether it is free of redundancies in necessary or sufficient conditions, structural redundancies, partial structural redundancies, whether it has constant factors or identical outcomes, and whether it is tautologous or contradictory.

Usage

```r
is.inus(cond, x = NULL, csf.info = FALSE)
```

Arguments

- **cond**: Character vector of DNFs or expressions in the syntax of CNA solutions (i.e. asf or csf).
- **x**: An optional argument providing a configTable, a data frame, or a list specifying the factors’ value ranges if `cond` contains multi-value factors; if `x` is not `NULL`, `is.inus` tests whether `cond` has INUS form relative to `full.ct(x)`, otherwise relative to `full.ct(cond)`.
- **csf.info**: Logical; if `TRUE` and `cond` has the syntax of a csf, details about the performed INUS checks are printed. If `cond` does not have the syntax of a csf, `csf.info` has no effect.

Details

A Boolean dependency structure is not interpretable in terms of a deterministic causal structure if it contains at least one of the following (cf. the “Examples” section for examples):

1. redundancies in necessary or sufficient conditions,
2. structural redundancies,
3. partial structural redundancies,
4. constant factors,
5. tautologous or contradictory substructures,
6. multiple instances of the same outcome.

The function `is.inus` takes a character vector `cond` specifying Boolean disjunctive normal forms (DNFs) or expressions in the syntax of CNA solution formulas as input and runs a series of checks on `cond`; one for each of the conditions (1) to (6). For instance, whenever a syntactic proper part of `cond` is logically equivalent to `cond` itself, the surplus in the latter is redundant, meaning that `cond` violates condition (1) and is not causally interpretable. To illustrate, “A + a*B <-> C” is logically equivalent to “A + B <-> C” and, hence, “a” redundant in the first expression, which is not causally
is.inus
interpretible due to a violation of condition (1). Or the first asf in “(a + C <-> D)*(D + G <-> A)” entails that whenever "a" is given, so is "D", while the second asf entails that whenever "D" is given, so is "A". It follows that "a" cannot ever be given, meaning that the factor A takes the constant value 1 and, hence, violates condition (4). As constant factors can neither be causes nor effects, “(a + C <-> D)*(D + G <-> A)” is not a well-formed causal structure.

If an expression passes the is.inus-check it can be interpreted as a causal structure according to Mackie’s (1974) INUS-theory of causation or modern variants thereof (e.g. Grasshoff and May 2001; Baumgartner and Falk 2019). In other words, such an expression has the form of an INUS structure, i.e. it has INUS form, for short.

In the function’s default call with \( x = \text{NULL} \), the INUS checks are performed relative to \( \text{full.ct}(\text{cond}) \); if \( x \) is not \( \text{NULL} \), the checks are performed relative to \( \text{full.ct}(x) \). As \( \text{full.ct}(\text{cond}) \) and \( \text{full.ct}(x) \) coincide in case of binary factors, the argument \( x \) has no effect in the crisp-set and fuzzy-set cases. In case of multi-value factors, however, the argument \( x \) should be specified in order to define the factors’ value ranges (see examples below).

If the argument csf.info is set to its non-default value \( \text{TRUE} \) and \( \text{cond} \) has the syntax of a csf, the results of the individual checks of conditions (1) to (6) are printed (in that order) to the console.

In its default setting, the cna function does not output solutions that do not have INUS form. But when cna is called with is.inus.only = \( \text{FALSE} \), non-INUS solutions may be returned. The function is.inus is standardly called from within the cna function to determine whether its output has INUS form.

is.inus also serves an important purpose in the context of benchmark tests. Not any Boolean expression can be interpreted to represent a causal structure; only expressions in INUS form can. That means when simulating data on randomly drawn target structures, it must be ensured that the latter have INUS form. An expression as “A + a\(^a\)B <-> C”, which has a logically equivalent proper part and, hence, does not have INUS form, is not a well-formed causal structure that could be used as a search target in a benchmark test.

Value

Logical vector of the same length as \( \text{cond} \); if \( \text{cond} \) is a csf and is.inus is called with csf.info = \( \text{TRUE} \), an attribute “csf.info” is added.

# A csf entailing that one factor is constant.
is.submodel

Identify correctness-preserving submodel relations

Description

The function is.submodel checks for each element of a vector of cna solution formulas whether it is a submodel of a specified target model y. If y is the true model in an inverse search (i.e. the ground truth), is.submodel identifies the correct models in the cna output (see Baumgartner and Thiem 2020, Baumgartner and Ambuehl 2020).

Usage

is.submodel(x, y, strict = FALSE)
identical.model(x, y)

Arguments

x Character vector of atomic and/or complex solution formulas (asf/csf). Must be of length 1 in identical.model.
y Character string of length 1 specifying the target asf or csf.
strict Logical; if TRUE, the elements of x only count as submodels of y if they are proper parts of y (i.e. not identical to y).

Details

To benchmark the reliability of a method of causal inference it must be tested to what degree the method recovers the true data generating structure Δ or proper substructures of Δ from data of varying quality. Reliability benchmarking is done in so-called inverse searches, which reverse the order of causal discovery as normally conducted in scientific practice. An inverse search comprises three steps: (1) a causal structure Δ is drawn/presupposed (as ground truth), (2) artificial data δ is simulated from Δ, possibly featuring various deficiencies (e.g. noise, limited diversity, measurement error etc.), and (3) δ is processed by the benchmarked method in order to check whether its output meets the tested reliability benchmark (e.g. whether the output is true of or identical to Δ).

The main purpose of is.submodel is to execute step (3) of an inverse search that is tailor-made to test the reliability of cna [with randomConds and selectCases designed for steps (1) and (2), respectively]. A solution formula x being a submodel of a target formula y means that all the causal claims entailed by x are true of y, which is the case if a causal interpretation of x entails conjunctive and disjunctive causal relevance relations that are all likewise entailed by a causal interpretation of y. More specifically, x is a submodel of y if, and only if, the following conditions are satisfied: (i)

is.inus("(S + L <-> P)*(L*p <-> JSR)", csf.info = TRUE)
# A contradictory csf.
is.inus("(S <-> JSR)*(JSR <-> s)", fsdata, csf.info = TRUE)
# A csf with multiple identical outcomes.
is.inus("(S*C + V <-> JSR)*(R + P <-> JSR)", fsdata, csf.info = TRUE)
all factor values causally relevant according to \( x \) are also causally relevant according to \( y \), (ii) all factor values contained in two different disjuncts in \( x \) are also contained in two different disjuncts in \( y \), (iii) all factor values contained in the same conjunct in \( x \) are also contained in the same conjunct in \( y \), and (iv) if \( x \) is a csf with more than one asf, (i) to (iii) are satisfied for all asfs in \( x \). For more details see Baumgartner and Thiem (2020) or Baumgartner and Ambuehl (2020, online appendix).

The function \texttt{identical.model} returns \texttt{TRUE} only if \( x \) (which must be of length 1) and \( y \) are identical. It can be used to test whether \( y \) is completely recovered in an inverse search.

### Value

Logical vector of the same length as \( x \).

makeFuzzy  

Fuzzifying crisp-set data

Description
The makeFuzzy function fuzzifies crisp-set data to a customizable degree.

Usage
makeFuzzy(x, fuzzvalues = c(0, 0.05, 0.1), ...)

Arguments
x  Data frame, matrix, or configTable featuring crisp-set (binary) factors with values 1 and 0 only.
fuzzvalues  Numeric vector of values from the interval [0,1].
...  Additional arguments are passed to configTable.

Details
In combination with allCombs, full.ct and selectCases, makeFuzzy is useful for simulating fuzzy-set data, which are needed for inverse search trials benchmarking the output of cna. makeFuzzy transforms a data frame or configTable x consisting of crisp-set (binary) factors into a fuzzy-set configTable by adding values selected at random from the argument fuzzvalues to the 0’s and subtracting them from the 1’s in x. fuzzvalues is a numeric vector of values from the interval [0,1].

selectCases can be used before and selectCases1 after the fuzzification to select those configurations that are compatible with a given data generating causal structure (see examples below).

Value
A configTable of type "fs".
minimalize

Eliminate logical redundancies from Boolean expressions

Description

minimalize eliminates logical redundancies from a Boolean expression cond based on all configurations of the factors in cond that are possible according to classical Boolean logic. That is, minimalize performs logical (i.e. not data-driven) redundancy elimination. The output is a set of redundancy-free DNFs that are logically equivalent to cond.

Usage

minimalize(cond, x = NULL, maxstep = c(4, 4, 12))

Arguments

cond Character vector specifying Boolean expressions; the acceptable syntax is the same as that of condition.
minimalize

- **x**: A data frame, a `configTable`, or a list determining the possible values for each factor in `cond`; `x` has no effect for a `cond` with only binary factors but is mandatory for a `cond` with multi-value factors (see details).

- **maxstep**: Maximal complexity of the returned redundancy-free DNFs (see `cna`).

**Details**

The regularity theory of causation underlying CNA conceives of causes as parts of redundancy-free Boolean dependency structures. Boolean dependency structures tend to contain a host of redundancies. Redundancies may obtain relative to an analyzed set of empirical data, which, typically, are fragmented and do not feature all logically possible configurations, or they may obtain for principled logical reasons, that is, relative to all configurations that are possible according to Boolean logic. Whether a Boolean expression (in disjunctive normal form) contains the latter type of logical redundancies can be checked with the function `is.inus`.

`minimalize` eliminates logical redundancies from `cond` and outputs all redundancy-free disjunctive normal forms (DNF) (within some complexity range given by `maxstep`) that are logically equivalent with `cond`. If `cond` is redundancy-free, no reduction is possible and `minimalize` returns `cond` itself (possibly as an element of multiple logically equivalent redundancy-free DNFs). If `cond` is not redundancy-free, a `cna` with `con = 1` and `cov = 1` is performed relative to `full.ct(x)` (relative to `full.ct(cond)` if `x` is `NULL`). The output is the set of all redundancy-free DNFs in the complexity range given by `maxstep` that are logically equivalent to `cond`.

The purpose of the optional argument `x` is to determine the space of possible values of the factors in `cond`. If all factors in `cond` are binary, `x` is optional and without influence on the output of `minimalize`. If some factors in `cond` are multi-value, `minimalize` needs to be given the range of these values. `x` can be a data frame or `configTable` listing all possible value configurations or simply a list of the possible values for each factor in `cond` (see examples).

The argument `maxstep`, which is identical to the corresponding argument in `cna`, specifies the maximal complexity of the returned DNF. `maxstep` expects a vector of three integers `c(i,j,k)` determining that the generated DNFs have maximally `j` disjuncts with maximally `i` conjuncts each and a total of maximally `k` factor values. The default is `maxstep = c(4,4,12)`. If the complexity range of the search space given by `maxstep` is too low, it may happen that nothing is returned (accompanied by a corresponding warning message). In that case, the `maxstep` values need to be increased.

**Value**

A list of character vectors of the same length as `cond`. Each list element contains one or several redundancy-free disjunctive normal forms (DNFs) that are logically equivalent to `cond`.

**See Also**

`condition, is.inus, cna, full.ct`.

**Examples**

# Binary expressions
# ------------------
# DNFs as input.

```r
# Binary expressions
# ------------------
# DNFs as input.
```
minimalizeCsf

Eliminate structural redundancies from csf

Description

minimalizeCsf eliminates structural redundancies from complex solution formulas (csf) by recursively testing their component atomic solution formulas (asf) for redundancy and eliminating the redundant ones.

Usage

minimalizeCsf(x, ...)

# Default S3 method:
minimalizeCsf(x, ct = NULL, verbose = FALSE, ..., data)
# S3 method for class 'cna'
minimalizeCsf(x, n = 20, verbose = FALSE, ...)
Arguments

- **x**
  In the default method, x is a character vector of csf. The cna method uses the strings representing the csf contained in an output object of cna (see details).

- **ct**
  Data frame, matrix or configTable with the data; optional if all factors in x are binary but required if some factors are multi-value. In the default case, ct is NULL and a dataset containing all possible configurations of the variables in the condition x is used.

- **verbose**
  Logical; if TRUE additional messages on the number of csf that are found to be reducible are printed.

- **n**
  Minimal number of csf to use.

- **...**
  Further arguments passed to the methods.

- **data**
  Argument data is deprecated in minimalizeCsf(); use ct instead.

Details

As of version 3.0 of the cna package, the function minimalizeCsf is automatically executed, where needed, by the default calls of the cna and csf functions. In consequence, applying the stand-alone minimalizeCsf function to an output object of cna is no longer required. The stand-alone function is kept in the package for reasons of backwards compatibility and for developing purposes. Its automatic execution can be suppressed by calling csf with minimalizeCsf = FALSE, which emulates outputs of older versions of the package.

The core criterion that Boolean dependency structures must satisfy in order to be causally interpretable is redundancy-freeness. In atomic solution formulas (asf), both sufficient and necessary conditions are completely free of redundant elements. However, when asf are conjunctively combined to complex solution formulas (csf), new redundancies may arise. A csf may contain redundant parts. To illustrate, assume that a csf is composed of three asf: asf1 * asf2 * asf3. It can happen that the conjunction asf1 * asf2 * asf3 is logically equivalent to a proper part of itself, say, to asf1 * asf2. In that case, asf3 is a so-called structural redundancy in asf1 * asf2 * asf3 and must not be causally interpreted. See the package vignette (vignette("cna")) or Baumgartner and Falk (2019) for more details.

minimalizeCsf recursively tests the asf contained in a csf for structural redundancies and eliminates the redundant ones. It takes a character vector x specifying csf as input and builds all redundancy-free csf that can be inferred from x. There are two possibilities to use minimalizeCsf. Either the csf to be tested for structural redundancies is passed to minimalizeCsf as a character vector (this is the default method), or minimalizeCsf is applied directly to the output of cna—which however, as indicated above, is superfluous as of version 3.0 of the cna package.

As a test for structural redundancies amounts to a test of logical equivalencies, it must be conducted relative to all logically possible configurations of the factors in x. That space of logical possibilities is generated by full.ct(x) if the ct argument takes its default value. If all factors in x are binary, providing a non-default ct value is optional and without influence on the output of minimalizeCsf.

If some factors in x are multi-value, minimalizeCsf needs to be given the range of these values by means of the ct argument. ct can be a data frame or configTable listing all possible value configurations.

Value

minimalizeCsf returns an object of class "minimalizeCsf", essentially a data frame.

minimalizeCsf("(f + a*D <-> C)*(C + A*B <-> D)*(c + a*E <-> F)"
   , verbose = TRUE) # Same result, but with some messages.

# The cna method.
dat1 <- selectCases("(C + A*B <-> D)*(c + a*E <-> F)")
ana1 <- cna(dat1, details = c("r"), inus.only = FALSE)
csf(ana1, minimalizeCsf = FALSE)

# The attribute "redundant" taking the value TRUE in ana1 shows that this csf contains
# at least one redundant element. Applying minimalizeCsf() identifies and removes
# the redundant element.
minimalizeCsf(ana1)
randomConds

Arguments

x
Data frame or configTable; determines the number of factors, their names and their possible values. In randomAsf, x must have >=3 columns, in randomCsf, x must have >=4 columns. As a shorthand, x can also be an integer, in which case full.ct(x) is executed first.

outcome
Optional character vector (of length 1 in randomAsf) specifying the outcome factor values in the solution formula. Must be factor values, e.g. "A" or "b" in case of binary data or "A=1" in case of multi-value data. With multi-value data, factor names are also allowed; a value of that factor will then be chosen at random. outcome overrides positive and n.asf.

positive
Logical; if TRUE (default), the outcomes all have positive values. If FALSE, a value (positive or negative in case of binary data) will be picked at random. positive has no effect if the outcome argument is not NULL or if x contains multi-value data.

maxVarNum
Maximal number of factors in x that can appear in the generated asf or csf. The default depends on the type of the data contained in x.

compl
Integer vector specifying the maximal complexity of the formula (i.e. number of factors in msc; number of msc in asf).

how
Character string, either "inus" or "minimal", specifying whether the generated solution formula is redundancy-free relative to full.ct(x) or relative to x (see details).

n.asf
Integer scalar specifying the number of asf in the csf. Is overridden by length(outcome) if outcome is not NULL. Note that n.asf is limited to ncol(x)-2.

Details

randomAsf and randomCsf can be used to randomly draw data generating structures (ground truths) in inverse search trials benchmarking the output of cna. In the regularity theoretic context in which the CNA method is embedded, a causal structure is a redundancy-free Boolean dependency structure. Hence, randomAsf and randomCsf both produce redundancy-free Boolean dependency structures. randomAsf generates structures with one outcome, i.e. atomic solution formulas (asf), randomCsf generates structures with multiple outcomes, i.e. complex solution formulas (csf), that are free of cyclic substructures. In a nutshell, randomAsf proceeds by, first, randomly drawing disjunctive normal forms (DNFs) and by, second, eliminating redundancies from these DNFs. randomCsf essentially consists in repeated executions of randomAsf.

The only mandatory argument of randomAsf and randomCsf is a data frame or a configTable x defining the factors (with their possible values) from which the generated asf and csf shall be drawn.

The optional argument outcome determines which values of which factors in x shall be treated as outcomes. If outcome = NULL (default), randomAsf and randomCsf randomly draw factor values from x to be treated as outcome(s). If positive = TRUE (default), only positive outcome values are chosen in case of crisp-set data; if positive = FALSE, outcomes values are drawn from the set {1,0} at random. positive only has an effect if x contains crisp-set data and outcome = NULL.

The maximal number of factors included in the generated asf and csf can be controlled via the argument maxVarNum. This is relevant when x is of high dimension, as generating solution formulas
with more than 20 factors is computationally demanding and, accordingly, may take a long time (or
even exhaust computer memory).

The argument compl controls the complexity of the generated asf and csf. More specifically, the
*initial* complexity of asf and csf (i.e. the number of factors included in msc and the number of msc
included in asf prior to redundancy elimination) is drawn from the vector compl. As this complexity
might be reduced in the subsequent process of redundancy elimination, issued asf or csf will often
have lower complexity than specified in compl. The default value of compl is determined by the
number of columns in x. Assigning unduly high values to compl results in an error.

randomAsf has the additional argument how with the two possible values "inus" and "minimal".
how = "inus" determines that the generated asf is redundancy-free relative to all logically possible
configurations of the factors in x, i.e. relative to full.ct(x), whereas in case of how = "minimal"
redundancy-freeness is imposed only relative to all configurations actually contained in x, i.e. relative
to x itself. Typically "inus" should be used; the value "minimal" is relevant mainly in repeated
randomAsf calls from within randomCsf. Moreover, setting how = "minimal" will return an error
if x is a configTable of type "fs".

The argument n.asf controls the number of asf in the generated csf. Its value is limited to ncol(x)-2
and overridden by length(outcome), if outcome is not NULL. Analogously to compl, n.asf spec-
ifies the number of asf prior to redundancy elimination, which, in turn, may further reduce these
numbers. That is, n.asf provides an upper bound for the number of asf in the resulting csf.

**Value**

The randomly generated formula, a character string.

redundant

Identify structurally redundant asf in a csf

Description

redundant takes a character vector cond containing complex solution formulas (csf) as input and tests for each element of cond whether the atomic solution formulas (asf) it consists of are structurally redundant.

Usage

redundant(cond, x = NULL, simplify = TRUE)

Arguments

- **cond**: Character vector specifying complex solution formulas (csf); only strings of type csf are allowed, meaning conjunctions of one or more asf.
- **x**: An optional argument providing a configTable, a data frame, or a list specifying the factors’ value ranges if cond contains multi-value factors; if x is not NULL, cond is tested for redundancy-freeness relative to full.ct(x), otherwise relative to full.ct(cond).
- **simplify**: Logical; if TRUE, the result for csfs with the same number of component asfs is presented as a matrix, otherwise all results are presented as a list of logical vectors.

Details

According to the regularity theory of causation underlying CNA, a Boolean dependency structure is causally interpretable only if it does not contain any redundant elements. Boolean dependency structures may feature various types of redundancies, one of which are so-called structural redundancies. A csf $\Phi$ has a structural redundancy if, and only if, reducing $\Phi$ by one or more of the asf it is composed of results in a csf $\Phi'$ that is logically equivalent to $\Phi$. To illustrate, suppose that $\Phi$ is composed of three asf: asf1 * asf2 * asf3; and suppose that $\Phi$ is logically equivalent to $\Phi'$: asf1 * asf2. In that case, asf3 makes no difference to the behavior of the factors in $\Phi$ and $\Phi'$; it is structurally redundant and, accordingly, must not be causally interpreted. For more details see the package vignette (vignette("cna")) or Baumgartner and Falk (2019).

The function redundant takes a character vector cond composed of csf as input and tests for each element of cond whether it is structurally redundant or not. As a test for structural redundancies amounts to a test of logical equivalencies, it must be conducted relative to all logically possible configurations of the factors in cond. That space of logical possibilities is generated by full.ct(cond) in case of x = NULL, and by full.ct(x) otherwise. If all factors in cond are binary, x is optional and without influence on the output of redundant. If some factors in cond are multi-value, redundant
needs to be given the range of these values. x can be a data frame or configTable listing all possible value configurations or a list of the possible values for each factor in cond.

If redundant returns TRUE for a csf, that csf must not be causally interpreted but further processed by minimalizeCsf. As of version 3.0 of the cna package, standard calls of the cna and csf functions automatically eliminate all structurally redundant asf.

Value

A list of logical vectors or a logical matrix.

If all csf in cond have the same number of asf and simplify = TRUE, the result is a logical matrix with length(cond) rows and the number of columns corresponds to the number of asf in each csf. In all other cases, a list of logical vectors of the same length as cond is returned.

Examples

# Binary factors.
cond1 <- c("(f + a*D <-> C)*(C + A*B <-> D)*(c + a*E <-> F)", "f + a*D <-> C")
redundant(cond1)

edu.sol <- csf(cna(d.educate), inus.only = FALSE)$condition
redundant(edu.sol, d.educate)
redundant(edu.sol, d.educate, simplify = FALSE)

# Default application of csf() with automatic elimination of structural redundancies.
ct.pban <- configTable(d.pban)
cna.pban <- cna(ct.pban, con = .75, cov = .75)
csf.pban <- csf(cna.pban)
redundant(csf.pban$condition, ct.pban)# no solutions with structural redundancies are returned
# Non-default application of csf() without automatic elimination of structural redundancies.
csf.pban <- csf(cna.pban, inus.only = FALSE)
redundant(csf.pban$condition, ct.pban)# various solutions with structural redundancies are # returned

# If no x is specified defining the factors' value ranges, the space of
# logically possible configurations is limited to the factor values contained in
```r
# cond, resulting in structural redundancies that disappear as soon as x is specified.
cond2 <- "(C=0+F=0 + G=1<-> T=2)*(T=2 + G=2 <-> P=1)"
redundant(cond2)
redundant(cond2, list(C=0:2, F=0:2, G=0:3, T=0:2, P=0:2))
```

---

### `rreduce`

**Eliminate redundancies from a disjunctive normal form (DNF)**

**Description**

`rreduce` eliminates redundancies from disjunctive normal forms (DNF), i.e. disjunctions of conjunctions of literals. If there are several minimal DNF, `rreduce` selects one at random.

**Usage**

```r
rreduce(cond, x = full.ct(cond), niter = 1, full = !missing(x), verbose = FALSE, 
maxiter = 1000, simplify2constant = TRUE)
```

**Arguments**

- `cond`  
  A character string specifying a disjunctive normal form; can be either crisp-set or multi-value.

- `x`  
  A configTable or data.frame; can be either crisp-set or multi-value.

- `niter`  
  An integer value \( \geq 1 \) specifying the number iterated minimization attempts. The minimal DNFs produced in each iteration are collected and returned.

- `full`  
  Logical; if TRUE (the default), redundancies are eliminated relative to full.ct(x), otherwise relative to x.

- `simplify2constant`  
  Logical; if TRUE (the default), a tautologous or contradictory cond is reduced to a constant "1" or "0", respectively. If FALSE, a minimal tautology or contradiction, i.e. "A+a" or "A*a", will result.

- `verbose`  
  Logical; if TRUE, the reduction process will be traced in the console.

- `maxiter`  
  Maximal number of iterations. This is a parameter of internal nature, usually not set by the user.

**Details**

`rreduce` successively eliminates conjuncts and disjuncts from a DNF `cond` as long as the result of `condition(cond, x)` remains the same. The only required argument is `cond`. If `x` is not provided, redundancies are eliminated relative to full.ct(cond). If `x` is provided and `full = TRUE`, redundancies are eliminated relative to full.ct(x). If `x` is provided and `full = FALSE`, redundancies are eliminated relative to `x`.

If `cond` has more than one redundancy-free form, `rreduce` only returns a randomly chosen one in the default setting of `niter = 1`. By increasing `niter` to a value \( \geq 1 \), cond is (randomly) minimized `niter` times. All resulting redundancy-free forms are collected and returned. This provides some insight about the amount of redundancy-free forms that `cond` has.
selectCases

Value

Redundancy-free disjunctive normal form (DNF).

full.ct.

Examples

# Logical redundancies.
cond1 <- "A*b + a*B + A*C + B*C"
  rreduce(cond1)
  rreduce(cond1, niter = 10)
cond2 <- "A*b + a*B + A*B + a*b"
  rreduce(cond2, simplify2constant = FALSE)

# Any Boolean expressions.
cond <- "!(A*B*C)*!(a*b*c)" # or "A + B*!(D + e) <-> C"
x <- selectCases(cond)
  cond <- getCond(x) # Returns a DNF equivalent to cond, but with many redundancies.
  rreduce(cond) # Repeated execution results in different outputs.
  rreduce(cond, verbose = TRUE)
  rreduce(cond, niter = 20) # 20 iterations yield 5 minimal forms.

selectCases

Select the cases/configurations compatible with a data generating causal structure

Description

selectCases selects the cases/configurations that are compatible with a Boolean function, in particular (but not exclusively), a data generating causal structure, from a data frame or configTable. selectCases1 allows for setting consistency (con) and coverage (cov) thresholds. It then selects cases/configurations that are compatible with the data generating structure to degrees con and cov.

Usage

selectCases(cond, x = full.ct(cond), type = "auto", cutoff = 0.5,
  rm.dup.factors = FALSE, rm.const.factors = FALSE)
selectCases1(cond, x = full.ct(cond), type = "auto", con = 1, cov = 1,
  rm.dup.factors = FALSE, rm.const.factors = FALSE)

Arguments

cond Character string specifying the Boolean function for which compatible cases are to be selected.

x Data frame or configTable; if not specified, full.ct(cond) is used.

Details

In combination with allCombs, full.ct, randomConds and makeFuzzy, selectCases is useful for simulating data, which are needed for inverse search trials benchmarking the output of the cna function.

selectCases draws those cases/configurations from a data frame or configTable x that are compatible with a data generating causal structure (or any other Boolean or set-theoretic function), which is given to selectCases as a character string cond. If the argument x is not specified, configurations are drawn from full.ct(cond). cond can be a condition of any of the three types of conditions, boolean, atomic or complex (see condition). To illustrate, if the data generating structure is "A + B <-> C", then a case featuring A=1, B=0, and C=1 is selected by selectCases, whereas a case featuring A=1, B=0, and C=0 is not (because according to the data generating structure, A=1 must be associated with C=1, which is violated in the latter case). The type of the data frame is automatically detected by default, but can be manually specified by giving the argument type one of its non-default values: "cs" (crisp-set), "mv" (multi-value), and "fs" (fuzzy-set).

selectCases1 allows for providing consistency (con) and coverage (cov) thresholds, such that some cases that are incompatible with cond are also drawn, as long as con and cov remain satisfied. The solution is identified by an algorithm aiming to find a subset of maximal size meeting the con and cov requirements. In contrast to selectCases, selectCases1 only accepts a condition of type atomic as its cond argument, i.e. an atomic solution formula. Data drawn by selectCases1 can only be modeled with consistency = con and coverage = cov.

Value

A configTable.

See Also

allCombs, full.ct, randomConds, makeFuzzy, configTable, condition, cna, d.jobsecurity

Examples

# Generate all configurations of 5 dichotomous factors that are compatible with the causal # chain (A*b + a*B <-> C) * (C*d + c*D <-> E).
groundTruth.1 <- "(A*b + a*B <-> C) * (C*d + c*D <-> E)"
(dat1 <- selectCases(groundTruth.1))
condition(groundTruth.1, dat1)
some <- Randomly select configurations from a data frame or configTable

Description

The function some randomly selects configurations from a data frame or configTable with or without replacement.

Usage

some(x, ...)

## S3 method for class 'data.frame'
some(x, n = 10, replace = TRUE, ...)
some(x, n = 10, replace = TRUE, ...)

Arguments

- **x**: Data frame or configTable.
- **n**: Sample size.
- **replace**: Logical; if TRUE, configurations are sampled with replacement.
- **...**: Not used.

Details

The function `some` randomly samples configurations from `x`, which is a data frame or configTable. Such samples can, for instance, be used to simulate data fragmentation (limited diversity), i.e. the failure to observe/measure all configurations that are compatible with a data generating causal structure. They can also be used to simulate large-N data featuring multiple cases instantiating each configuration.

Value

A data frame or configTable.

Note

The generic function `some` is read from the package `car`. The method for `data.frame`s in the `cna` package has an additional parameter `replace`, which is TRUE by default. It will thus not apply the same sampling scheme as the method in `car` by default.
